Overview of the Randomized Trials of Radiotherapy in Ductal Carcinoma In Situ of the Breast

Early Breast Cancer Trialists' Collaborative Group (EBCTCG)

Correspondence to: EBCTCG Secretariat, Clinical Trial Service Unit (CTSU), Richard Doll Bldg, Old Road Campus, University of Oxford, Oxford OX3 7LF, United Kingdom (e-mail: bc.overview@ctsu.ox.ac.uk).

Individual patient data were available for all four of the randomized trials that began before 1995, and that compared adjuvant radiotherapy vs no radiotherapy following breast-conserving surgery for ductal carcinoma in situ (DCIS). A total of 3729 women were eligible for analysis. Radiotherapy reduced the absolute 10-year risk of any ipsilateral breast event (ie, either recurrent DCIS or invasive cancer) by 15.2% (SE 1.6%, 12.9% vs 28.1% 2 P <.00001), and it was effective regardless of the age at diagnosis, extent of breast-conserving surgery, use of tamoxifen, method of DCIS detection, margin status, focality, grade, comedonecrosis, architecture, or tumor size. The proportional reduction in ipsilateral breast events was greater in older than in younger women (2P < .0004 for difference between proportional reductions; 10-year absolute risks: 18.5% vs 29.1% at ages <50 years, 10.8% vs 27.8% at ages ≥50 years) but did not differ significantly according to any other available factor. Even for women with negative margins and small low-grade tumors, the absolute reduction in the 10-year risk of ipsilateral breast events was 18.0% (SE 5.5, 12.1% vs 30.1%, 2P = .002). After 10 years of follow-up, there was, however, no significant effect on breast cancer mortality, mortality from causes other than breast cancer, or all-cause mortality.

J Natl Cancer Inst Monogr 2010;41:162–177

Until the 1980s, ductal carcinoma in situ (DCIS) of the breast was usually treated by mastectomy. However, following the introduction of breast-conserving therapy for the treatment of early-stage invasive breast cancer, local excision of DCIS with or without radiotherapy to the conserved breast began to be used and, from 1985 to 1990, four randomized trials comparing adjuvant radiotherapy vs no radiotherapy following local excision for DCIS were initiated. We report here an overview of their results based on individual patient data.

Methods

Every 5 years since 1985, evidence from the randomized trials in early breast cancer has been reviewed centrally in a worldwide collaboration between the individuals responsible for them (the Early Breast Cancer Trialists’ Collaborative Group [EBCTCG]). Two 2005 EBCTCG reports gave the results up to the year 2000 from the trials that began recruitment by 1995 of adjuvant systemic treatments (studying various types of chemotherapy or hormonal therapy) (1) and of local treatments (studying various types of surgery and/or adjuvant radiotherapy) (2). The present report uses similar methods and gives the results up to September 2006 of the trials that began by 1995 of adjuvant radiotherapy vs no radiotherapy following local excision for DCIS.

Trial Identification and Main Outcomes

Trial identification procedures were as in previous EBCTCG reports. Only unconfounded trials were sought (ie, trials in which there was to be no difference between the treatment groups in the extent of surgery or in the use of systemic therapy). Five trials were identified that began by 2000, and brief design details are given in Table 1. One trial (Radiation Therapy Oncology Group 9804) began only in 1999 and is not yet available. The remaining four began in 1985–1990 and have provided information for each patient on characteristics at diagnosis, allocated treatment, time to first event and whether the event was ipsilateral recurrence of DCIS, ipsilateral occurrence of invasive breast cancer, occurrence of contralateral DCIS or contralateral invasive breast cancer, or regional or distant metastasis of breast cancer. Information was also provided on cause-specific mortality and incident non-breast primary cancers. It was assumed that any death attributed to breast cancer had been preceded by metastatic breast cancer.

Data Management

Data management procedures were as in recent EBCTCG reports (1,2) except that for each woman additional clinical and pathological details were sought about her disease. This information could have been gathered during later pathological review, provided that it was based on material obtained at the time of initial diagnosis or treatment, and provided that samples had not been selected for pathological review according to allocated treatment or outcome.

Statistical Analysis

Analyses were based on allocated treatment and were stratified by trial and time since randomization in single years. The analyses...

† After exclusion of women with a benign lesion only or with microinvasion, invasion, Paget’s disease, other cancer present at randomization, or other study-specific protocol violation.
‡ Including information from later pathological reviews, provided that it was based on material obtained at the time of initial diagnosis or treatment and provided that samples had not been selected for pathological review according to allocated treatment or outcome.
§ Microinvasion (<1 mm) allowed, present in 0.3%. A total of 1684 women were randomized in this trial. However, 664 were women randomized in a comparison of tamoxifen vs not. They have therefore been excluded from the present overview. A total of 540 of the 1002 women included in the overview were randomized to radiotherapy and tamoxifen vs tamoxifen alone, while the remainder were randomized to radiotherapy vs not.

Collaborative Review
A preliminary meta-analysis of these trials was presented and discussed at a meeting of collaborators in September 2006, after which much additional information was sought about clinical and pathological details and about outcomes. Revised meta-analyses were presented at the National Institutes of Health State-of-the-Science Conference on DCIS in September 2009 and were circulated for comment by collaborating EBCTCG trialists. A draft of the present report was circulated for comment to the trialists in December 2009, and the manuscript was revised in the light of comments received.

Results
A total of 3925 women were randomized and, after exclusion of those who had only a benign lesion at the time of randomization, or who already had microinvasion, invasion, Paget’s disease or another cancer present at the time of initial diagnosis, or who had another study-specific protocol violation, a total of 3729 remained eligible for the analysis. A total of 21% of them were randomized during 1985–1989, 46% during 1990–1995, and 32% during 1995–2000. Median follow-up was 8.9 woman-years. A total of 924 women were reported as having experienced a breast event after randomization, and 74% of the first events were in the ipsilateral breast (Table 2).
Radiotherapy approximately halved the rate of ipsilateral breast events (rate ratio 0.46, standard error [SE] 0.05, 2 \( P < .00001 \)). At 5 years after randomization the absolute reduction in risk was 10.5% (SE 1.2%, 7.6% vs 18.1%) while at 10 years it was 15.2% (SE 1.6%, 12.9% vs 28.1%) (Figure 1). By 10 years after randomization 192 of the women allocated to BCS+RT had had an ipsilateral breast event, and for 100 of them it was a recurrence of DCIS while for the remaining 92 women it was an invasive cancer. The corresponding numbers for the women allocated to BCS were 218 with a recurrence of DCIS and 204 with an invasive cancer. Thus for both endpoints the number of events observed was approximately halved. The rate of ipsilateral breast events was approximately halved in all four trials, with no evidence of heterogeneity between the trials in the proportional reduction (Figure 2).

Radiotherapy was effective in reducing ipsilateral breast events regardless of whether the woman was aged younger than or older than 50 years at diagnosis, whether local excision or sector resection had been performed, and whether or not tamoxifen was to be given to both treatment arms or to neither (Figure 3). For each other characteristic, information was unavailable for many women. Nevertheless, the information that was available sufficed to show that radiotherapy was effective in reducing ipsilateral breast events regardless of whether the original tumor was detected by mammography only or by clinical symptoms, whether the excised lesion had negative margins, and whether the tumor was unifocal.
architecture (Figure 6), and of clinical or pathological tumor size (Figure 7).

Radiotherapy resulted in a larger proportional reduction in the rate of ipsilateral breast recurrence for women aged more than 50 years than for younger women (rate ratios: age <50 years 0.69, SE 0.12; ≥50 years 0.38, SE 0.06, 2P = .0004 for the difference between these proportional reductions), but the proportional reduction did not differ significantly according to any other factor (Figure 8). When the data were subdivided into five groups according to age (<40, 40–49, 50–59, 60–69, ≥70), the trend in the proportional reduction with age was significant (P = .02). The difference between the proportional reductions in younger and older women did not appear to be accounted for by differences in histological grade or comedonecrosis (Figure 9) or by differences in nuclear grade or architecture (data not shown).

Women with negative margins and small low-grade tumors were identified a priori as a group expected to be at low absolute risk of ipsilateral breast events, for whom radiotherapy might therefore provide little absolute gain. However, information was often unavailable on one or more of these factors, so only 291 such women could be studied. Among them, the 10-year risk of an ipsilateral event in those allocated not to receive radiotherapy was, however, substantial at 30.1% (SE 5.5%) (Figure 10, left-hand panel).

Other End-Points

Radiotherapy reduced the risk of any breast event (ie ipsilateral recurrence of DCIS, ipsilateral occurrence of invasive breast cancer, contralateral occurrence of DCIS or invasive breast cancer, or regional or distant metastasis of breast cancer) (rate ratio 0.59, SE 0.05, P < .00001), and at 5 years after randomization the absolute reduction was 9.3% (SE 1.3%, 11.3% vs 20.7%), while at 10 years it was 11.5% (SE 1.7%, 21.2% vs 32.7%) (Figure 11). In this analysis, which considered first events only, women who were allocated to radiotherapy experienced higher risks compared with those allocated to no radiotherapy for both contralateral and regional or distant events but neither difference was significant (contralateral rate ratio 1.16, SE 0.16 2P > .1; regional or distant rate ratio 1.51, SE 0.34, 2P > .1).

A total of 353 women were known to have died during follow-up, 96 from breast cancer, 217 from other causes (including 55 from heart disease), and 40 for whom the cause of death was unknown (Table 3). For breast cancer mortality and for mortality from all causes, women who were allocated to radiotherapy experienced slightly higher risks compared with those allocated to no radiotherapy (breast cancer mortality rate ratio 1.22, SE 0.18, 2P > .1; all-cause mortality rate ratio 1.11, SE 0.11, 2P > .1) (Figure 12). Mortality from causes other than breast cancer in the period before a breast event and mortality from heart disease were also slightly higher among women allocated to radiotherapy, but the increases were not significant (all-cause mortality rate ratio 1.04 SE 0.15, 2P > .1; heart disease rate ratio: 1.11, SE 0.33, 2P > .1). A total of 74 non-breast primary cancers were reported during follow-up, but there was no evidence that radiotherapy had any net effect on the incidence of such cancers (rate ratio 0.99, SE 0.20, 2P > .1).

Discussion

These randomized trials provide strong and consistent evidence that, in the populations studied, radiotherapy after breast-conserving surgery for DCIS approximately halved the rate of ipsilateral breast recurrence.
Figure 3. Effect of radiotherapy (RT) after breast-conserving surgery (BCS): 10-year cumulative risks of any ipsilateral breast event by age at diagnosis, extent of surgery, and use of tamoxifen (3729 women). Women given sector resection were from either the SweDCIS trial (1011 women) or the EORTC 10853 trial (135 women), and women using tamoxifen were all in the UK/ANZ DCIS trial. Information was not available on estrogen or progesterone receptor status.

Vertical lines indicate 1 SE above or below the 5 and 10 year percentages.

breast events during the subsequent decade with little effect on contralateral or distant events. The absolute magnitude of the 10-year risk reduction was 15%, and in the irradiated group both the number of women with recurrent DCIS and the number of women with invasive breast cancer in the conserved breast were substantially reduced. The proportional reduction in the rate of ipsilateral breast events achieved with radiotherapy was greater in older than in younger women but did not differ significantly according to any other factor. The age effect did not appear to be accounted for by younger women being more likely to have high-grade lesions or...
Method of DCIS detection

Figure 4. Effect of radiotherapy (RT) after breast-conserving surgery (BCS): 10-year cumulative risks of any ipsilateral breast event by detection method (2619 women), margin status (3355 women) and focality (1526 women). Women for whom the surgical margins were close (<2 mm) were classified as having negative surgical margins. Vertical lines indicate 1 SE above or below the 5 and 10 year percentages.
comedonecrosis, and the explanation for it is unknown. A radiotherapy boost was rarely used (Table 1), and so the impact of a boost in DCIS could not be assessed.

In these trials, in most of which tamoxifen was not given, 12.9% of women allocated to radiotherapy had an ipsilateral breast event within the first decade. This risk is similar to that in a large multi-institutional series of women diagnosed up to 1995 and given breast-conserving surgery with radiotherapy (14), suggesting that the women in these trials were reasonably typical of women diagnosed with DCIS during that era. Since then, breast screening has become more common, so in recent years women diagnosed with DCIS tend to have smaller lesions. In addition, greater attention is now paid to achieving negative surgical margins. Both factors are associated with a lower rate of ipsilateral breast events in the absence of radiotherapy. Therefore, there has been considerable interest in identifying patients with favorable features for whom the rate of ipsilateral breast events in the absence of radiotherapy is so low that radiotherapy can reasonably safely be omitted (15–17).

In the data available from these trials, it was not possible to subdivide women with tumors smaller than 20 mm according to tumor size. Therefore, all women with negative margin status and low-grade tumors smaller than 20 mm were combined in our “low-risk” group. These criteria are less stringent than those used in recent nonrandomized studies (15–17) to define low risk, which could well explain the higher risk of ipsilateral breast events in the “low-risk” women in these trials. The trial results suggest, however, that no matter what the underlying rate of ipsilateral breast events may be for particular categories of women, it will be approximately halved by radiotherapy.

The risks of a contralateral breast event and of a regional or distant breast event both appeared to be somewhat larger among the women allocated to radiotherapy than among the controls. Neither of these increases was statistically significant and so chance may be the explanation for them. However, the analyses presented in this article consider only first events and make the assumption that women who experience an ipsilateral breast event are no more or less likely than other women to experience a regional, distant, or contralateral event. This independence assumption cannot be verified from the data. If women with more aggressive disease are at greater risk of all three types of event, then, as the predominant effect of the radiotherapy is on ipsilateral

Figure 5. Effect of radiotherapy (RT) after breast-conserving surgery (BCS): 10-year cumulative risks of any ipsilateral breast event by histological grade (1794 women) and nuclear grade (1617 women).

Vertical lines indicate 1 SE above or below the 5 and 10 year percentages.
events, the apparent slight increase in the risk of contralateral and regional or distant events may be an artifact accounted for by events that would, in the absence of radiotherapy, have occurred after an ipsilateral breast event. The analysis of any breast event does not depend on the independence assumption and confirms the efficacy of radiotherapy in reducing breast events overall.

In these randomized trials, the risk of death from breast cancer was non-significantly greater in the women allocated to radiotherapy than in the women allocated to breast-conserving surgery only, as was the risk of death from all causes. Breast cancer mortality is unlikely to be affected by the issues referred to in the previous paragraph, while mortality from all causes cannot be affected by it. Therefore, as the differences are not significant, chance seems a likely explanation for them.

Among the much larger numbers of women in the trials of radiotherapy following breast-conserving surgery for early invasive breast cancer, radiotherapy had little effect on breast cancer mortality during the first few years of follow-up, but, by 15 years, about one breast cancer death was avoided for every four local recurrences avoided in the first 5 years (2). Theoretically, if about the same 1:4 ratio applied to ipsilateral invasive cancers following breast-conserving therapy for DCIS, then radiotherapy might be expected to reduce breast cancer mortality by an absolute amount of about 1% or 2% by year 15 or 20, which the present trials can neither exclude nor confirm.

Notes
The writing committee for this paper were: C. Correa, P. McGale, C. Taylor, Y. Wang, M. Clarke, C. Davies, R. Peto, N. Bijker, L. Solin, and S. Darby. The EBCTCG secretariat in the Clinical Trial Service Unit, University of Oxford (listed above) accept full responsibility for the overall content of this report.

The writing committee and secretariat declare that they have no conflict of interest.

The main acknowledgment is to the thousands of women who took part in the trials reviewed here. Funding for the EBCTCG secretariat is from the general long-term financial support from the Cancer Research UK and the UK Medical Research Council to the Clinical Trial Service Unit and Epidemiological Studies Unit (CTSU), University of Oxford. These organisations had no role in study design, data collection, data analysis, data interpretation, or writing of the report.
